ABSTRACT

Background: Pneumonia acquired outside the hospital by an immune-competent individual is defined as community acquired pneumonia (CAP). It is to be distinguished, on the basis of a wider spectrum of pathogens, from nosocomial pneumonia from pneumonia in an immune-compromised host. Community-acquired pneumonia is associated with a significant mortality and morbidity. Etiology of CAP varies geographically and the understanding of local epidemiology plays an important role in decision making for empirical treatment before test results are available. Primary decisions about empirical antimicrobial treatment required knowledge of predominant microbial patterns and their sensitivities.

Objectives: The aim of this study was to identify the bacterial etiology of CAP, their sensitivity towards empirical therapy and to observe the clinical course as well as short term outcome in hospitalized adult patients.

Methodology: It was one year-long observational prospective study on 87 patients diagnosed with CAP admitted in Chattogram Medical College Hospital, second largest tertiary care hospital during August 2018 to July 2019. Sputum for Gram and Z-N staining, culture and sensitivity, blood for

*Corresponding author: E-mail: morshednasir@hotmail.com, morshed@hfrcmc.edu.bd;
culture, sensitivity and PCR for Streptococcus pneumonia, Mycoplasma pneumoniae, Legionella pneumophila and Chlamyphila pneumonia were done. Patients were followed up for in-hospital outcome and 30-day mortality.

**Results:** The mean age was 49.59 years and male - female ratio was 1.56: 1. Fever, chest pain and cough were the most common clinical findings. Klebsiella pneumoniae was identified (39.1%) in the majority of the patients, followed by Pseudomonas aeruginosa (10.3%), Staphylococcus aureus and Escherichia coli (5.7%). Staphylococcus aureus was positive in blood culture of one patient. Four samples were positive in PCR and identified Streptococcus pneumoniae. The sensitivity to meropenem, levofloxacin and amikacin was highest. The mean duration of hospital stay was 6.34 ± 2.37 days along with in-hospital mortality and 30-day mortality was 6.9% and 16.1% respectively.

**Conclusion:** The bacteriologic profile of community acquired pneumonia revealed Gram-negative bacteria as pre-dominant organism by conventional sputum and blood culture. But need for further serologic tests for atypical and viral pathogens and development of institutional antibiogram to facilitate the choice for empirical therapy is required.

**Keywords:** Community Acquired Pneumonia (CAP); antimicrobials; antibiotic resistance; CURB-65.

1. **INTRODUCTION**

“Infectious pneumonia is the acute invasion of lung parenchyma by one or more viral, bacterial, fungal or parasitic pathogens. The invasion of the lung is rarely verified in vivo, and is usually substituted by the presence of a new permeate on radiological studies” [1]. “A person presenting with acute cough and any of the suggestive sign or symptom like localized findings on chest examination, fever lasting more than four days, presence of dyspnea or tachypnoea is suspected as pneumonia. It may also manifested by acute confusion or loss of functionality in geriatric patients. Evidence of an acute infiltrate on radiological studies differentiates pneumonia from acute bronchitis, a benign, self-resolving condition that does not require antibiotic treatment” [2].

“Recently, a new category named ‘healthcare-associated pneumonia’ and including patients living in nursing homes, recently hospitalized, or in frequent contact with the healthcare system (eg. undergoing hemodialysis or ambulatory chemotherapy) has been proposed, but its relevance is strongly debated and not widely accepted in Europe” [3]. Due to major differences in the epidemiology, management, and prognosis, a distinction is made between pneumonia in a patient living at home (CAP), in a patient already hospitalized (hospital-acquired pneumonia), and in a patient with severe immunosuppression.

“The community acquired pneumonia (CAP) is generally known as the pneumonia acquired outside the hospital to an immune-competent individual. It differs from nosocomial pneumonia that occurs after 48 hours of admission or within 3 months of discharge from hospital, and from typical pneumonia in an immune-compromised host, on the basis of wider variety of pathogens. Immune-compromised condition implies in the setting of neutropenia, iatrogenic immunesuppression with drugs, organ or stem-cell transplantation, HIV infection, or a congenital immune deficiency in a person” [4,5].

“Chronic obstructive pulmonary disease, conceded immune system, gastro esophageal reflux disease, etc. increase susceptibility of a patient for pneumonia [6]. Particular forms of antimicrobial resistance of habitual pathogens may also contribute otherwise” [7]. “The acquaintance of these microbiological characteristics is important and represents the basis for empirical treatments. Serious co-existing illness has been identified as modifying factors of severity of pneumonia” [6,8]. “On the basis of these, specific criteria for antibiotic selection and the management of patients were set in the guidelines for pneumonia in the presence of co-morbid diseases” [9].

“While many cases of mild to moderate CAP can be successfully managed without identification of the organism, a range of microbiological tests should be performed on patients with severe CAP that required hospitalization. The common etiological agents causing CAP include Streptococcus pneumonia (20-60%), Hemophilus influenza (3-10%), Chlamydia pneumonia (4-6%), Mycoplasma pneumonia (1-6%), Legionella (2-8%), Staphylococcus aureus (3-5%), Gram-negative bacilli (3-5%), viruses (2-13%). In 40-
60% cases, no cause is identified and in 2-5% cases, two or more pathogens are identified" [10]. However, the epidemiology of bacterial infection varies depending on the geographic location. Peto et al. demonstrated that, in Asia these organisms were identified in a higher proportion of patients [11]. Conversely, although S. pneumoniae was commonly identified, it was relatively less important than in most European studies. Also, a substantial proportion of patients presenting with CAP in Asian countries were found to have TB, which is often considered to cause only more chronic pulmonary disease. Finally, B. pseudomallei was a major cause of CAP in northeast Thailand and was also reported in other Southeast Asian countries.

Hence the present study focuses on the clinico-bacteriological profile in cases of CAP for a better clinical approach. A benchmark data and regular surveillance data regarding bacteriology of CAP and sensitivity pattern is essential to address the problem of CAP among hospitalized patients. These findings will provide clinicians in this region of Bangladesh with a better understanding of the spectrum of pathogens, updated knowledge about their antibiotic susceptibility pattern and in selecting the antibiotic for empirical therapy in hospitalized patients with CAP.

2. METHODOLOGY

The prospective observational study was conducted from August 2018 to July 2019 in the Department of Medicine of Chittagong Medical College Hospital, the second largest government hospital in the country. Patients of both sexes age above 18 years who were diagnosed as CAP admitted in the Department of Medicine was included in the study as consecutive sampling method. The objective of the study was to isolate and identify the causative bacteria and their sensitivity pattern, describe clinical presentation, in-hospital complication and short term clinical outcome during hospital stay for CAP.

Sputum for Gram and Z-N staining, culture and sensitivity, blood for culture, sensitivity and PCR for Streptococcus pneumonia, Mycoplasma pneumoniae, Legionella pneumophila and Chlamydiophila pneumonia were done. Total 85 admitted patients were included after screening of exclusion criteria. Patient on immunosuppressive drugs, steroids and chemotherapy and getting antibiotic for more than 48 hours were excluded. After admission in the indoor, any suspected case of CAP seen by unit doctor was screened by study physician. Evaluation was made by history and physical examination in a structured case record form (CRF) by the study physician. Patients diagnosed clinically as CAP were enrolled in the study. Socio demographic variables (age, sex, residential area, religion, monthly family income), risk factor of pneumonia (smoking habit, immunization history), clinical parameters (weight, length, height, chief complain, examination findings, CURBE-65 score), complete blood count (TC of WBC, Hb%, ESR), chest X-ray, RBS, Blood urea, blood culture, sputum for Gram staining and culture sensitivity, sputum for AFB for 3 consecutive samples were done. Duration of hospital stay, improvement, referral to ICU, development of complications during the hospital course was recorded besides the short-term outcome of 30-days mortality or survival.

Antibiotic therapy of the enrolled patient was given at the discretion of the treating clinician under the supervision of respective consultant of the medicine unit. The clinical judgment of consultant was ascertained by CURB-65 score by the study physician. During treatment, oral temperature was recorded and frequently physical examinations were performed up to discharge. Patients were asked to report 30 days after discharge for follow up.

Microbiological laboratory tests: “Sputum originated from the lower respiratory tract and cultured in blood agar, chocolate agar and MacConkey’s agar media. Primary blood cultures were done in Trypticase soya broth and secondary blood cultures were done on blood agar, chocolate agar and MacConkey’s agar media” [15].

Sputum microscopy and culture: “Specimens were classified by Bartlett's Criteria; Bacterial morphological types were screened at oil immersion field. Blood agar media was used for primary isolation and study of hemolytic property of the organism, Chocolate agar media for isolation of fastidious organisms and MacConkey agar media for isolation of Gram negative organisms” [15]. For the simplified method, bacteria with almost pure growth with colony numbers of more than twenty-five on the plate were defined as pathogens. Identification of bacteria were done by colony morphology, Gram stain, biochemical test. Sputum samples were stored at -80°C for further use.
Susceptibility testing by disc diffusion: Antimicrobial susceptibility was determined by the disc diffusion method of modified Kirby-Bauer technique, using Blood agar media (for Streptococcus pneumoniae), Mueller-Hinton agar media (for Escherichia coli, Klebsiella and Pseudomonas). The turbidity of the inoculums was standardized to the equivalent to that of 0.5 McFarland standard. All plates were incubated at 37°C aerobically for Blood agar and Mueller-Hinton agar.

Antimicrobial agents used (CLSI 2017): Following antimicrobials and their concentration per disc were used for susceptibility tests as for i) Gram positive cocci and diplococci: Meropenem (10 microgram), Ceftriaxone (30 microgram), Amoxiclav (30 microgram), Levofloxacine (5 microgram), Azithromycine (1 microgram), Cefexime (30 microgram) and Vancomycine (30 microgram). ii) For Gram negative bacilli and cocobacilli: Meropenem (10 microgram) Ceftriaxone (30 microgram) Amikacin (10 microgram), Azithromycine (15microgram), Levofloxacine (5 microgram), Amoxiclav (30 microgram) and Cefexime (30 microgram). The antibiotic sensitivity testing discs were manufactured by Oxoid Ltd, UK.

Polymerase chain reaction: PCR was done in the Department of Microbiology of CMCH after collection of all samples for Streptococcus pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumoniae and Legionella pneumophila.

Quality control was ensured by testing representative disc from each batch against reference strains of E. coli ATCC 25922 and S. aureus ATCC 25923; zones of inhibition were tested with standard value (CLSI 2017). After collection data were entered into Microsoft Xcel data sheet to produce a master sheet. Then they were fed into SPSS version 23 software for the processing and analyses. Continuous variables were reported as means and standard deviation and categorical variables were reported as count and percentages. For categorical data, the Chi square test or Fisher exact test were used to compare groups. The confidence interval was set at the 95 percent level, and statistical significance was defined as P < 0.05.

3. OBSERVATIONS AND RESULTS

The mean age was 49.59±16.97 years with ranged from 18 to 76 years and maximum number (35.6%) of patients was found in the age group of 40-59 years. There was male predominance with a male to female ratio of 1.56:1.

About half of the enrolled patients were either current smoker or ex-smoker. One third (27.8%) of the patients had history of DM and majority of the DM patients had uncontrolled glycemic status (Table II).

Cough was present in all of the study patients. Fever and chest pain were also frequently reported by 86 patients while, respiratory distress was reported by 72 (82.8%) and hemoptysis was reported by 17 (19.5%) patients (Fig. 1).

![Graph showing presenting symptoms of the 87 admitted patients with CAP](image-url-for-fig-1)
Bronchial breath sound was the most prominent respiratory findings observed in 85 (97.7%) of the patients followed by tachypnea in 43 (49.4%) and crepitation in 36 (41.4%) patients (Fig. 2). More than half of the patients were malnourished and one fifth of them were obese as per BMI criteria.

Different laboratory findings of the enrolled CAP patients are presented in Table III. It shows that, sputum gram stain was positive in 55 (63.2%) patients while Z-N stain was negative in entire sample. Sputum culture yield growth in 53 (60.9%) sample while blood culture only in 1 (1.1%) sample. PCR was positive in 4 (4.6%) sample.

Out of 87 admitted CAP patients, majority of them either had 0 CURB-65 score (31/87) or 1 CURB-65 score (30/87). Only 11 (13.7%) patients had CURB-65 score 3 or more.

Klebsiella pneumoniae was identified in the majority of the patients (39.1%), followed by Pseudomonas aeruginosa, Staphylococcus aureus and Escherichia coli. Only one sample was positive with Staphylococcus aureus in blood culture. Streptococcus pneumoniae was identified in four positive cases by PCR. Average length of hospital stay was 6 days. About one tenth of the total patients develop
sepsis and need ICU support besides the mortality rate of the CAP patients was 6.9% and 30-day mortality rate was 14.1%.

Table II shows that, patients who died within 30 days, majority had either Klebsiella pneumonia or Pseudomonas aeruginosa. Among survivors in addition of these two organisms Staphylococcus aureus, Escherichia coli and Streptococcus pneumonia were identified.

During admission severity of pneumonia was assessed by CURB-65 score. Patients with severe disease (CURB-65 >2) and with less severe disease (CURB-65 ≤2) have almost similar bacteriological pattern.

Overall the isolated organisms in the study were found to be highly sensitive for Meropenem (96.2%), Amikacin (96.2%), Levofloxacin (88.5%) and Vancomycin (80.0%).

4. DISCUSSION

“The maximum numbers of cases of CAP (70%) were aged more than 40 years with a mean age of around 50 years. According to the earlier studies by Naik et al. the average age was around 53 years” [12] but differ with the study of Salam et al. conducted in Bangladesh where the corresponding figure was comparatively lower (39 years) [13]. However, in a study conducted among the adult population of USA reported that the median age of the patients was 57 years [14]. This variation in their study may be due to higher life expectancy in their population.

“The microbial diagnosis of CAP was confirmed in 65.5% of patients with standard sputum culture, blood culture and PCR test. However, this rate varies in different studies with different laboratory testing in 29%, 49% and 75.6% cases in different studies among Indians respectively” [12,15]. “Comparatively high incidence of the etiological diagnosis in the present study is probably explained by the strict inclusion criteria. Patients with a history of getting antibiotic for more than 48 hours were excluded from the present study. The possible causes for the inability to determine specific causative organism in patients were lack of sensitivity of laboratory investigations, prior antibiotic treatment and lack of more sophisticated investigations. Other prospective studies for evaluating the causes of CAP in adults have failed in 40 - 60% of cases to establish an etiologic diagnosis” [14,16].

Fever and cough were most common symptoms whereas bronchial breath sound on affected side and crepitation were the commonest signs observed in the present study. Almost similar observations regarding the clinical presentations were also reported by other studies among hospitalized patients13,17. Sign of consolidation like bronchial breath sound was found in 98% cases in the present study and similarly Salam et al. found consolidation in almost all study patients.

“The mean duration of hospital stay (6.34 ± 2.37 days) was similar to few other studies where the mean duration of hospital stay was 5.0±1.7 days and 5±1.2 days” [13,18]. “The in-hospital mortality rate during index admission and 30-day mortality was 6.9% and 16.1% respectively in the present study but the mortality rate of CAP in various hospital-based studies is variable, being 2% in a population of USA” [14] to a higher mortality of 25% in Europe in earlier studies [19].

Prognosis of the patient was seen in hospitalized patient through CURB score. Out of 87 patients 61 patients in this study had CURB-65 score within score-1. Only 13.7% patients had CURB-65 score 3 or more in this study. Nine CAP cases in present study were needed to be shifted to ICU as they developed sepsis.

“It was observed that isolated strain of Klebsiella was mostly resistant to the antibiotics commonly used for CAP (amoxiclav, cefixime, cefuroxime, clarithromycin and ceftazidime) in present study. Other isolated organisms were also resistant to β-lactamase inhibitor, macrolides and third generation cephalosporin. Whereas, meropenem, amikacin and levofloxacin were the most responsive antibiotics for the organisms identified form the CAP patients. However, meropenem is costly and not recommended by the guideline published by American thoracic society and infectious disease society of America” [20]. “Multi drug resistant to β-lactam, macrolides and fluoroquinolone is an emerging problem and complicating the management of CAP” [21]. “In a study in Dhaka Medical College Hospital reported that, the sensitivity pattern of isolated strain of bacteria from CAP patients was alarming and the resistant bacteria were emerging” [13]. The study was conducted over nine months which might be a constraint to detect the less common pathogens during the study.
5. CONCLUSION

The present study revealed that the Gram-negative bacilli like Klebsiella pneumonia, Escherichia coli and Pseudomonas aeruginosa were common organism for CAP identified by sputum culture. A bigger and broader nationwide study can be helpful to obtain vast and accurate epidemiological data on CAP in Bangladesh. In addition, the unidentified causes of hospital deaths highlight the necessity of additional research in patients who may have risk factors for poor prognosis at the time of admission in order to initiate treatment early and lower mortality. Regional differences in bacteriological profile as well as their sensitivity pattern should be considered during selecting the best and sensitive drugs for treating CAP. Institutional antibiogram should be developed to facilitate the choice for empirical therapy. Future investigations including large sample sizes with serologic tests for atypical and viral infections from multiple centres are crucial to determining the whole etiological range of CAP.

CONSENT AND ETHICAL APPROVAL

The consent from patients and approval from Institutional Ethics Board (IRB) was taken prior to the study accordingly.
